Abstract

We discuss criteria for designing an optimal “green field” proton driver for a neutrino factory. The driver parameters are determined by considerations of space charge, power capabilities of the target, beam loading and available RF peak power.

INTRODUCTION

A neutrino factory may be the best experimental tool to unravel the physics involved in neutrino oscillation and CP violation phenomena [1]. To achieve reasonable amount of data sufficient of acceptable resolution within 5 year operation time, 10^{21} protons on target is required, which translates into about 4 MW beam power from the proton driver.

In the past, there were individual proposals from different laboratories of a particular design of proton driver capable of delivering beam power from 2 to 4 MW, without consistent attention paid to the needs or requirements from the down stream systems. In this study, we try to identify the requirements from those down stream system first, then see whether it is possible to design a proton driver to meet those needs. Such a study will also assist site specific proposals to further improve on their design to better serve the need of a proton driver for neutrino factory application.

As shown in Fig.1, after the proton driver, there are several major subsystems comprising the complete configuration of a neutrino factory [2]. They are the target and horn system, the bunch rotation and capture system, the cooling system, the acceleration system, and finally the decay ring. Each of these systems requires the proton driver to have certain beam qualities for optimal performance.

The beam power of a proton driver depends on the energy, intensity and repetition rate of the proton beam, according to the relation, $P = E N e f$. To achieve, 4 MW, possible examples of beam intensity required at given energy and rep rate are shown in Table 1. It is important to realize that typically it requires a beam intensity at the level of 5×10^{13} per pulse, which is at about the limit of what can be reasonably achieved from our past experience, due to the limitation from space charge and other coherent instabilities.

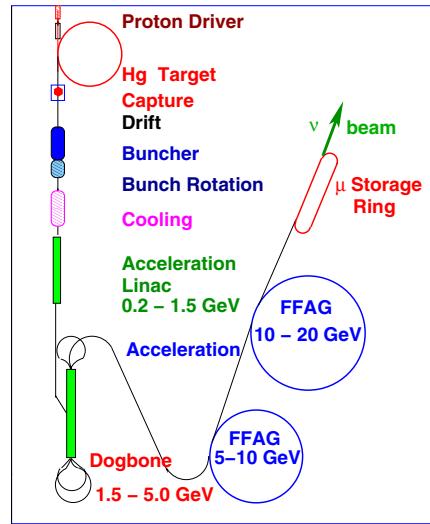

Figure 1: Schematic layout of a neutrino factory.

Therefore, special attention has to be paid to the choice of beam energy and number of bunches.

Table 1. Protons per pulse required for 4 MW. 1 Tp is 10^{12} protons.

	10 Hz	25 Hz	50 Hz
10 GeV	250 Tp	100 Tp	50 Tp
20 GeV	125 Tp	50 Tp	25 Tp

ENERGY CHOICE

We wish to determine kinetic energy of the proton beam which is most efficient for the production of soft-pions which will lead to the maximal collection of muons in a pion decay channel. We process the produced pions through the entire front end of the neutrino factory front end using the Study 2a [3] configuration from the target module to the conclusion of the cooling section. As a figure of merit, we select those surviving muons which are fully contained within the capture transverse acceptance ($30 \pi \text{ mm-rad}$) and the longitudinal acceptance ($150 \pi \text{ mm-rad}$) of the assumed subsequent accelerating section.

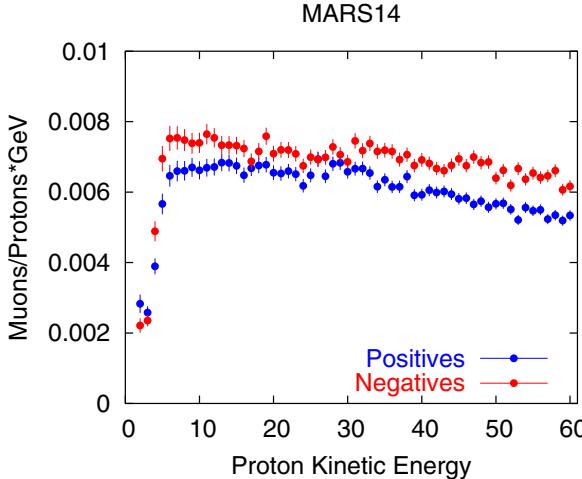

Figure 2: Efficiency of muon collection at the exit of the Study 2a front end versus proton driver energy.

The particle production model used was MARS V14 [4] and the propagation of the particles through the neutrino factory front end was done utilizing the ICOOL code [5]. The efficiency of the muon capture was done by evaluating the number of collected muons at the end of the neutrino factory front end and normalizing the results to the power of the proton beam such that a beam of e.g. 20GeV kinetic energy is assumed to contain twice the number of protons as an equivalent beam with 40GeV kinetic energy. Results of this analysis utilizing a mercury based target is shown in Fig. 2. The target parameters such as radius, tilt angle, and longitudinal placement has been previously optimized in Study 2a.

We also investigated other candidate target types with elements of various Z content with the result that the high-Z materials show the highest proficiency for soft-pion production which will lead to greatest number of captured muons. In evaluating the most efficient kinetic energy region we examine the production region within 10% of the maximum efficiency considering the sum of both positive and negative pions. We find this region to be 6 to 38 GeV.

TARGET ISSUES

The challenge of delivering 4 MW of power on a target (solid or liquid) is governed by two sets of parameters. The first set relates to the production target and specifically the choice of material, as well as its integrated design that allows it to operate as a functional unit. The second set is linked with the proton pulse structure delivered to the target and the parameter choices have a direct impact on the survivability of the target. Whether liquid or solid, the target feasibility issues stem from the inherent material limits that in turn are a function of the deposited energy density. The energy density is a result of

the pulse intensity, the proton energy, and pulse spatial structure as well as material density.

Solid vs. Liquid Targets

The issues associated with each of these two target types are distinctively different. On one hand, solid targets are vulnerable to thermo-mechanical shock induced by high energy densities that can lead to failure even with a single pulse on target. Fatigue due to the cyclic nature of the problem can lead to premature failure of the target. Most importantly, solid targets are susceptible to irradiation damage manifesting itself in altering the key properties of the material, both physical and mechanical that are responsible for shock absorbance and heat diffusion towards the heat sink. The onset of irradiation damage is always expected to compromise the longevity and functionality of a solid target. In addition solid targets, even under the best of circumstances, must enable the removal of the significant heat load through a feasible and “smart” design. This is particularly challenging because of the constraints brought onto the target by physics requirements that limit the size of the target to avoid re-absorption of secondary particles and thus limiting the available target surface area for heat transfer to the heat sink. Solid targets seem capable of reaching powers of 2 MW at best and only with low Z, high performance materials

Liquid targets on the other hand, either in the form of jets or contained volumes, do not suffer from thermal shock, fatigue or irradiation damage. While these serious limitations are avoided altogether, liquid targets face challenges of a different kind. Specifically, interaction of the proton beams with a high Z liquid jet target will lead to an explosive style destruction that, while of no consequence to the secondary particle production, could have serious consequences in the target infrastructure. The ability to replenish a liquid jet to meet the repetition requirement of the high power proton driver and the difficulties of adopting a feasible jet scheme to tight geometrical constraints pose additional challenges. In the case of a contained liquid, the generation of high cavitation pressures can induce damage on the target infrastructure. Liquid targets seem capable of supporting a 4 MW proton driver.

Proton Energy

While energy density distribution in a given solid target will vary within the target depending on the energy of the incoming protons, an important parameter in transferring deposited heat from the target, the maximum energy density increases with increasing energy. Table 2 depicts peak energy densities on a Cu target intercepting proton pulses with the same intensity and pulse shape. Therefore, for the energy region of interest of a 2-4 MW proton driver the lower energy would allow either pulse intensities to increase (leading to higher achievable power) or provide additional safety margins to the target.

Table 2: Energy Density in Cu Targets at Different Beam Energies (MCNPX Code)

proton energy (GeV)	8	16	24
energy density (J/g)	234	351	377

Repetition Rate

The benefit of increased repetition rate of the proton driver is two-fold. For a given proton driver power an increased rep-rate will lower the demand on the target (especially the solid target) in that the pulse intensity will be decreased. For the same pulse intensity and increased repetition rate the proton driver power increases but the demand on the target increases as well. Specifically, the thermal load of each pulse on the target must, under the higher rep-rate, be removed by the heat sink in a shorter time and the rep-rate limit will be controlled by the ability to remove the dynamic stresses entirely between pulses.

Pulse length, intensity and structure

The survivability of the target depends on the above three parameters. Specifically, the pulse intensity, combined with the beam spot size, controls the quasi-static conditions of pressure and temperature generated in the target upon beam interception. Energy densities of up to 400 J/g, corresponding to $\sim 24 \cdot 10^{12}$ protons-per-pulse and $\sigma = 1\text{mm}$, may be tolerated by some high performance solid materials. The pulse length controls the ensuing dynamic stresses and can play a significant role in the way the solid target survives the induced shock. Solid targets favor longer pulses because of the ability to relax during deposition. On the other hand, liquid jet targets will perform best at very short pulses (a few ns) where the onset of jet destruction has not occurred. A pulse structured not as a Gaussian but as a uniform distribution over the same (i.e., 3σ spot) and same intensity will reduce the stress and temperature demand on the target by approximately a factor of three.

BUNCH LENGTH

The effect of the proton bunch length at the target on the muon density is shown in Fig. 3. The accepted muon density at the end of the front end cooling channel falls off with increasing proton driver bunch length on the target. This behavior can be partially understood by a simple theory that models the longitudinal dynamics of the muon beam.

REPETITION RATE

The primary downside of a higher repetition rate is the average power consumption for the RF systems. There are two sources of this: the first is the energy to fill the RF cavities for each pulse (the unused portion of which we have no good way of storing for the next pulse), and the second is the cryogenic costs for cooling the dynamic heat load (the heat from the absorption of the cavities' stored energy) in the superconducting cavities.

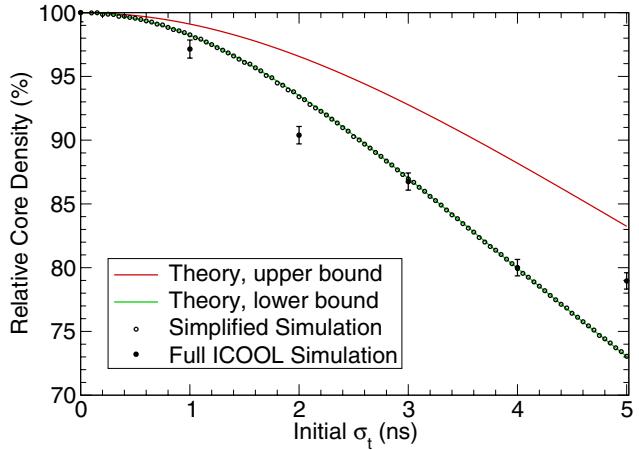

Figure 3: Muon density versus bunch length of the proton pulse at the target.

In Study II [6], the average power required for these systems was 44 MW for a 15 Hz average repetition rate. This portion of the machine's power consumption will be proportional to the repetition rate.

Higher repetition rates will reduce the amount of current per bunch train, which will as a result reduce the beam loading in the RF cavities. The primary effect of this is that the bunches toward the head of the train will gain more energy than those at the tail of the train, since the earlier bunches have extracted energy from the cavities. This would be corrected, at least partially, if particles were undergoing synchrotron oscillations, but they do not do so in the FFAGs, and they undergo a relatively small number of synchrotron oscillations in the RLAs and initial linac. Furthermore, some schemes for the storage ring require (superconducting) RF cavities to keep the beam bunched, and higher currents might require more RF power (and possibly more cavities) to compensate for beam loading there.
